**ABSTRACT:** Understanding the efficiency and variability of photochemical ozone ( $O_3$ ) production from western wildfire plumes is important to accurately estimate their influence on North American air quality. A set of photochemical measurements were made from the NOAA Twin Otter research aircraft as a part of the Fire Influence on Regional to Global Environments and Air Quality (FIREX-AQ) experiment. We use a zero-dimensional (0-D) box model to investigate the chemistry driving  $O_3$  production in modeled plumes. Modeled afternoon plumes reached a maximum  $O_3$  mixing ratio of  $140 \pm 50$  ppbv (average  $\pm$  standard deviation) within  $20 \pm 10$  min of emission compared to  $76 \pm 12$  ppbv in  $60 \pm 30$  min in evening plumes. Afternoon and evening maximum  $O_3$  isopleths indicate that plumes were near their peak in  $NO_x$  efficiency. A radical budget describes the  $NO_x$  volatile - organic compound (VOC) sensitivities of these plumes. Afternoon plumes displayed a rapid transition from VOC-sensitive to  $NO_x$ -sensitive chemistry, driven by  $HO_x$  ( $=OH + HO_2$ ) production from photolysis of nitrous acid (HONO) ( $48 \pm 20\%$  of primary  $HO_x$ ) and formaldehyde (HCHO) ( $26 \pm 9\%$ ) emitted directly from the fire. Evening plumes exhibit a slower transition from peak  $NO_x$  efficiency to VOC-sensitive  $O_3$  production caused by a reduction in photolysis rates and fire emissions.  $HO_x$  production in evening plumes is controlled by HONO photolysis ( $53 \pm 7\%$ ), HCHO photolysis ( $18 \pm 9\%$ ), and alkene ozonolysis ( $17 \pm 9\%$ ).

**KEYWORDS:** oxidation, volatile organic compounds, biomass, photodissociation, atmospheric chemistry

## 1. INTRODUCTION

Emissions from wildfires have significant and increasing impacts on local and regional air quality in the western United States (U.S.). Pollutants such as  $PM_{2.5}$  (particulate matter  $<2.5 \mu m$  aerodynamic diameter) and ozone ( $O_3$ ) regularly exceed U.S. National Ambient Air Quality Standards in the western U.S. nearly every fire season.<sup>1–7</sup> Ozone is a secondary pollutant, formed in the troposphere by the oxidation of volatile organic compounds (VOCs) in the presence of nitrogen oxides ( $NO_x = NO + NO_2$ ) and sunlight.<sup>8,9</sup> While biomass burning (BB), including wildfires, is estimated to contribute only 3.4% to total  $NO_x$  emissions in the United States,<sup>10,11</sup>  $NO_x$  emissions from fossil fuels have steadily declined, decreasing by 65% from 1990 to 2019.<sup>11</sup> Concurrently, western U.S. wildfire emissions have been increasing for two decades due to growing frequency and intensity of fires.<sup>12–14</sup> These trends are likely to continue due to decreasing

snowpack, increasing summertime temperatures, drought, and human-caused ignitions.<sup>15,16</sup>

Biomass burning emissions are rich in  $O_3$  precursors,<sup>17–19</sup> including VOCs, reactive nitrogen compounds, and photolytic radical sources. Reactive nitrogen in BB plumes includes  $NO_x$  and nitrous acid (HONO), the latter also being an important radical source.<sup>20</sup> Plumes from BB emit large amounts of highly reactive VOCs, including small oxygenates (e.g., formaldehyde, acetaldehyde), alkenes (e.g., ethene, propene, butene, 1,3-butadiene), aromatics (e.g., catechol, phenol, benzene, and

**Figure 1.** (a) Map of sampled fire complexes during FIREX-AQ, colored by O<sub>3</sub> mixing ratio. (b) Time series of jNO<sub>2</sub> (black trace) measured by the NOAA Twin Otter during a typical flight day (8/28/2019) and measured GOES-16 fire radiative power (FRP) for the Cow 4 fire (red dashed trace). Peak actinic flux (jNO<sub>2</sub>) and FRP occur during the afternoon sampling window (shaded in red). Evening plume sampling (shaded in blue) demonstrates a sharp decrease in actinic flux and a moderate decrease in FRP.

toluene), furans (e.g., furan, 2-furfural, furanone), and terpenes (e.g., isoprene, monoterpenes, oxygenated monoterpenes, and sesquiterpenes).<sup>21–25</sup> Several of these VOC classes are also photochemical radical sources, including formaldehyde (HCHO), glyoxal, and other aldehydes.

The relationships between O<sub>3</sub> and its major precursors (NO<sub>x</sub>, VOCs, and radical sources) follow well-known, nonlinear functions.<sup>9,26–29</sup> The relationship between O<sub>3</sub> and NO<sub>x</sub> is linear at low NO<sub>x</sub> mixing ratios (NO<sub>x</sub>-sensitive regime) but decreases with increasing NO<sub>x</sub> mixing ratios (VOC-sensitive regime). The NO<sub>x</sub> sensitivity of O<sub>3</sub> production can be defined by the relative amount of VOCs and radical

precursors.<sup>27,30</sup> The NO<sub>x</sub>–VOC–radical system, while well studied for urban areas, has received less attention in wildfire plumes, which are chemically complex. Recent laboratory studies and aircraft-based field campaigns have better defined BB emissions<sup>21,22,24,31,32</sup> by characterizing BBVOCs and major radical sources, which both differ from the urban case.<sup>33–38</sup> Understanding the NO<sub>x</sub>–VOC–radical sensitivity in BB plumes serves to better define their downwind impacts on air quality.

Analysis of aircraft observations of O<sub>3</sub> photochemistry in BB plumes remains limited despite an increasing number of recent investigations. A box modeling analysis during the 1992

SAFARI campaign emphasized the importance of properly parameterizing dilution with a conserved tracer (e.g., carbon monoxide (CO)).<sup>39,40</sup> Further, the 2000 SAFARI campaign in Otavia, Namibia, modeled O<sub>3</sub> production in young savanna BB plumes.<sup>41–43</sup> These savanna BB plumes displayed NO<sub>x</sub>-sensitive O<sub>3</sub> photochemistry controlled by HCHO photolysis and alkene ozonolysis as the major radical sources; NO<sub>x</sub> termination and reservoir species were mainly nitric acid (HNO<sub>3</sub>) and peroxy acetyl nitrate (PAN).<sup>43</sup> During the 2013 DISCOVER-AQ campaign, a young agricultural plume sampled in the southeast U.S. was analyzed using a box model and detailed VOC observations.<sup>44</sup> Elevated PAN mixing ratios downwind of two fires in the western U.S. and 15 agricultural fires in the southeastern U.S. were observed during the 2013 SEAC<sup>4</sup> RS campaign, indicating a significant NO<sub>x</sub> sink.<sup>17,45</sup> Most recently during the 2018 WE-CAN campaign in the northwestern U.S., HONO observations in wildfire BB plumes indicated HONO photolysis as a dominant primary HO<sub>x</sub> (=OH + HO<sub>2</sub>) source in early plume evolution.<sup>23,46</sup>

We present an analysis of aircraft measurements that includes detailed chemistry to constrain O<sub>3</sub> production and its sensitivities in BB plumes. In the summer of 2019, a major field campaign sampled tens of wildfires in the western U.S. The Fire Influence on Regional to global Environments and Air Quality (FIREX-AQ) deployed the NASA DC-8 and the NOAA Twin Otter research aircraft to sample wildfire plumes. We use the initial emissions and downwind chemical transformation as sampled by the NOAA Twin Otter to investigate O<sub>3</sub> formation. We show a detailed investigation of the NO<sub>x</sub>–VOC sensitivity of O<sub>3</sub> production during the first 2 h of plume evolution together with the primary HO<sub>x</sub> sources and radical sinks in the sampled plumes.

## 2. METHODS

**2.1. Platform and Instrumentation.** Measurements were conducted in situ from the NOAA Twin Otter during FIREX-AQ from 29 July to 5 September 2019. The aircraft was based in Boise, ID, from 29 July to 5 September, and briefly in Cedar City, UT, from 19 August to 23 August. We focus on relevant measurements of wildfire plumes including their chemical, physical, and optical characterizations. A summary of the measurements including methods, sampling frequency, uncertainties, and references used for this analysis is presented in Table 1. More information and data can be found at <https://csl.noaa.gov/projects/firex-aq/twinotterCHEM/>.

**2.2. Selected Fires and Plume Intercepts.** The NOAA Twin Otter sampled western wildfires during 40 research flights. We present the analysis of 11 research flights sampling seven fire complexes, which were selected for the time of day, the number of downwind transects, and full data coverage (map shown in Figure 1a). The dates, names, time of day, fuels, locations, burn size, GOES-16 24 h mean fire radiative power (FRP), average photolysis rate, number of plume transects, and histograms of CO are included in the Supporting Information (Table S1 and Figure S22).

The NOAA Twin Otter probed air masses as they advected downwind to investigate the chemical evolution with time. However, it not possible to maintain Lagrangian sampling (i.e., repeat sampling of the same air mass) in complex plume structure, terrain, and airspace. Thus, we deem our approach “semi-Lagrangian”. The average true airspeed for plume transects was  $71 \pm 0.2$  m s<sup>−1</sup>, yielding a spatial resolution of ~70 m for 1 Hz instruments. A typical time series obtained

during a semi-Lagrangian experiment is included in the Supporting Information (Figure S1).

**2.3. Plume Ages.** Plume ages were calculated taking both advection and plume rise into account.<sup>58</sup> Advection was determined using back trajectories from HYSPLIT using three different meteorological fields (HRRR 3 km, NAM CONUS nest 3 km, and GFS 0.25°). Vertical plume rise time was based on the height of the trajectory above the surface at the point in which it most closely approached the fire complex with an assumed mean vertical rise speed of 7 m s<sup>−1</sup> (50 ± 5% of total transport speed). Uncertainty in plume age is estimated from the range in ages computed with the three meteorological fields, with median uncertainty around 25% of the age. The age at the center of the plume (highest CO mixing ratio) was used for subsequent box modeling.

**2.4. Photochemical Box Modeling.** We simulated O<sub>3</sub> formation in BB plumes using the Framework for 0-D Atmospheric Modeling,<sup>59</sup> a photochemical zero-dimensional (0-D) box model. Near-field plume transects were limited by flight restrictions; thus, an iterative box model<sup>60,61</sup> was applied to investigate early plume chemistry. The gas-phase chemical mechanism implemented in this 0-D model was adapted from the Master Chemical Mechanism (MCMv3.3.1) with additional BBVOC oxidation reactions for furan, 2-methylfuran, 3-methylfuran, 2,5-dimethylfuran, furfural, 5-methylfurfural, methylguaiacol, guaiacol, and syringol.<sup>23,62</sup> Catechol, methyl catechol, dimethyl catechol, and benzoquinone oxidation were also updated in the MCM as described in the Supporting Information (Figure S2) based on experimental work by Finewax et al.<sup>63</sup> and Schwantes et al.<sup>64</sup> The MCM with additional BBVOCs<sup>23,62</sup> is a near-explicit mechanism used to characterize the gas-phase chemical processes involved in the degradation of over 143 VOCs.<sup>65,66</sup>

BBVOC emissions have been studied extensively as a function of both combustion conditions and fuel types commonly found in the western U.S.<sup>21–23,25,32,62,67</sup> In this work, a VOC emissions profile was developed using data compiled by Decker et al.,<sup>62</sup> based on measurements made during the 2012 FLAME-IV<sup>21</sup> and 2016 FIREX<sup>22</sup> (hereafter referred to as FIRELAB) laboratory experiments. This dataset comprises 302 of the most reactive BBVOCs measured at FIRELAB, and we use 48 of the most abundant in this study. The variability of VOC emissions was investigated by comparing the FIRELAB emissions ratio data<sup>32</sup> to the FIREX-AQ 2019 DC-8 observations and the 2012 FLAME-IV lab experiment to find an agreement within a factor of 2 among all studies (see Figures S3 and S4). Following these comparisons, the FIRELAB BBVOC emission profile was extended to an additional VOC emissions profile in which the FIRELAB BBVOC emissions were reduced by 50% as an extra VOC sensitivity case study (referred to as 0.5 FIRELAB) (Table S3).

The model was initialized using measured mixing ratios of NO, NO<sub>2</sub>, HONO, O<sub>3</sub>, CO, CH<sub>4</sub>, C<sub>6</sub>H<sub>6</sub>O (phenol), C<sub>6</sub>H<sub>6</sub>O<sub>2</sub> (catechol), and C<sub>7</sub>H<sub>8</sub>O (cresol) (see Table 1) measured at the densest part of the plume, as determined by the highest CO mixing ratio. This approach does not account for the plume center to edge variability in photochemical regimes. The low time resolution of the BBVOC data measured by two-dimensional (2-D) gas chromatography–mass spectrometry (GC–MS) required the use of derived VOC emissions profiles to initialize the model. Time-dependent BBVOC mixing ratios, based on the profiles described above, were compared with

observed BBVOCs from the  $I^-$  CIMS and 2-D GC–MS. The measured BBVOCs are in better agreement with the reduced VOC emissions profile (0.5 FIRELAB) (Figures S5, S6, and S13–S21) and the results from this profile are reported herein. The better agreement with the 0.5 FIRELAB case is possibly due to differences in modified combustion efficiency (MCE) between laboratory studies ( $0.93 \pm 0.02$ )<sup>68</sup> and real fire emissions (this study:  $0.89 \pm 0.02$ ; see Table S1); however, MCE relationships with VOC emissions are generally complex and sometimes poorly correlated.<sup>68–70</sup>

Dilution is an important physical process influencing the chemical evolution of fire plumes. An approximately conserved tracer (CO) was used to determine a first-order loss rate ( $k_{\text{dil}}$ ), which is applied to all chemical species in the box model. In some instances, regional background air had higher mixing ratios than in the plume for certain species ( $\text{CO}_2$ ,  $\text{O}_3$ ), in which case, dilution caused a mass increase of species into the plume.<sup>71</sup> Background mixing ratios were constrained to measurements made immediately outside of the plume for each flight (see Table S2 for  $k_{\text{dil}}$  and average background mixing ratios).

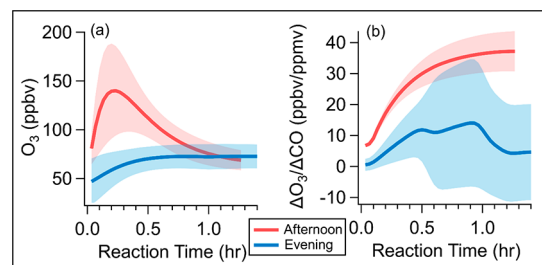

We developed a numerical iteration scheme to estimate the initial conditions required to fit observations downwind of each fire (description and model fit examples in Supporting Information Figures S5 and S6). Emission scaling factors for CO,  $\text{NO}_x$ , HONO, and the entire VOC profile are reported in the Supporting Information (Table S3). Additionally, HONO-to- $\text{NO}_x$  ratios (ppbv/ppbv) are provided after 30 min of oxidation (Table S3). The modeled fire plumes had an average HONO-to- $\text{NO}_x$  ratio of  $0.12 \pm 0.21$  after 30 min of oxidation, which is within the range of reported laboratory and field-based studies.<sup>19,20,46</sup> Generally, the modeled plumes underestimated first transect HONO-to- $\text{NO}_x$  ratio observations made on the NOAA Twin Otter ( $0.21 \pm 0.11$ ).

In addition to chemical constraints, the model was constrained with measured meteorological parameters (temperature, pressure, relative humidity, solar zenith angle, and  $\text{NO}_2$  photolysis rate). Photolysis rates were constrained with the MCM parameterization<sup>65</sup> and then scaled to the observed  $j\text{NO}_2$  measurements. This scaling approach allows the model to account for the plume darkening effect on photolysis rates, but does not account for spectral dependence. Stronger attenuation at shorter wavelengths may reduce photolysis rates for UV-absorbing molecules such as  $\text{O}_3$ , HCHO, or HONO smaller than modeled.

### 3. RESULTS AND DISCUSSION

The western wildfire plumes sampled from the Twin Otter in summer 2019 exhibited rapid photochemical production of  $\text{O}_3$ . Most of these plumes were from moderately sized fires (GOES-16 FRP 24 h mean range: 61–643 MW) that were not optically opaque, with average relative reductions in  $\text{NO}_2$  photolysis rates of  $27 \pm 22\%$  at the plume center, where the range represents one standard deviation of the mean. Results for more optically dense plumes from larger fires are likely to be different. Generally, both sets of models represented  $\text{O}_3$  mixing ratios downwind (average error  $\pm$  standard deviation); the 0.5 FIRELAB (overall:  $0.6 \pm 4\%$ ) profile matched initial plume transects ( $3.7 \pm 7\%$ ) more accurately than the FIRELAB (1st transect:  $14 \pm 16\%$ ) profile (overall:  $5.1 \pm 7\%$ ) (see Table S5). Modeled maximum  $\text{O}_3$  mixing ratios were reached within 60 min of emission for all modeled plumes. Initial  $\text{O}_3$  production rates (initial maximum slopes of Figure

2a) of afternoon plumes (12:00–17:00 MDT) were, on average, higher than evening plumes (17:00–20:45 MDT)

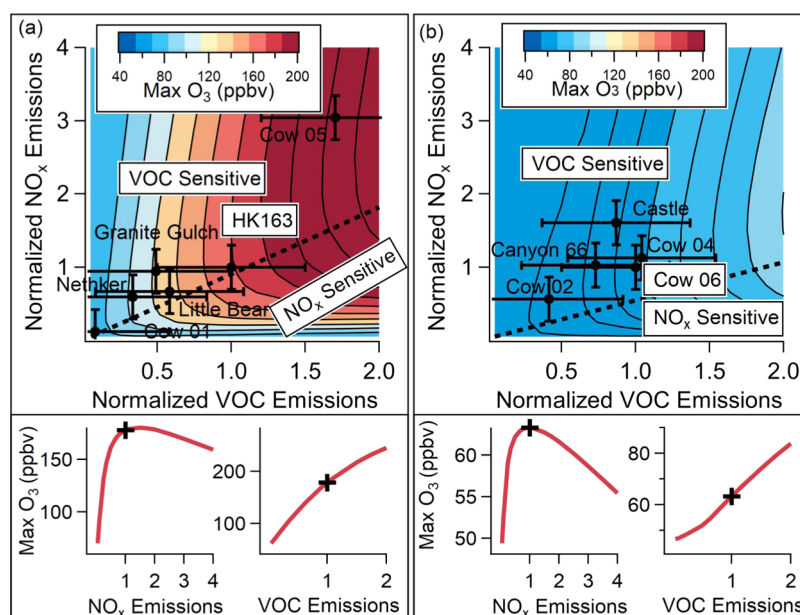

**Figure 2.** Modeled  $\text{O}_3$  mixing ratio using the 0.5 FIRELAB BBVOC emissions case. (a) Modeled  $\text{O}_3$  mixing ratio as a function of reaction time for all modeled fires averaged by time of day sampled. Shading represents one standard deviation. (b) Modeled normalized excess  $\text{O}_3$  mixing ratio as a function of reaction time for all modeled fires averaged by time of day sampled. Shading represents one standard deviation. Modeled  $\text{O}_x$  ( $\text{O}_3 + \text{NO}_2$ ) and normalized excess  $\text{O}_x$  mixing ratios as a function of reaction time display similar trends as  $\text{NO}_2$  makes up  $\sim 10\%$  of  $\text{O}_x$  (Figures S11 and S12).

( $500 \pm 60$  and  $66 \pm 2$  ppbv  $\text{h}^{-1}$ , respectively). These daytime  $\text{O}_3$  production rates are large compared to urban  $\text{O}_3$  production, which is typically 10–100 ppbv  $\text{h}^{-1}$  near source regions.<sup>72–75</sup> Modeled afternoon plumes reached an average maximum  $\text{O}_3$  mixing ratio of  $140 \pm 50$  ppbv within  $20 \pm 10$  min of emission compared to  $76 \pm 12$  ppbv in  $60 \pm 30$  min in evening plumes. The model exhibited more pronounced, rapid photochemical production of  $\text{O}_3$  in afternoon plumes due to rapid production of primary radicals that initiate oxidation reactions in the  $\text{NO}_x$ – $\text{HO}_x$  cycle. On average, afternoon fire plumes produced twice as much  $\text{O}_3$  in half the time as evening plumes. Dilution rates in the observed BB plumes were competitive with  $\text{O}_3$  production rates, oftentimes making  $\text{O}_3$  enhancements within the plume relatively small several hours downwind. The normalized excess mixing ratio (NEMR) accounts for plume dilution and entrainment of background air into the plume.

$$\text{NEMR}_{\text{O}_3} = \frac{\Delta\text{O}_3}{\Delta\text{CO}} = \frac{(\text{O}_3_{\text{plume}} - \text{O}_3_{\text{background}})}{(\text{CO}_{\text{plume}} - \text{CO}_{\text{background}})}$$

The highest  $\text{NEMR}_{\text{O}_3}$  rate (maximum slope in Figure 2b) was observed in the afternoon plumes, reaching  $65 \pm 3$  ppbv  $\text{O}_3$  ppmv  $\text{CO}^{-1} \text{h}^{-1}$  (Figure 2b). The evening  $\text{NEMR}_{\text{O}_3}$  rate reached a maximum on average of  $43 \pm 1$  ppbv  $\text{O}_3$  ppmv  $\text{CO}^{-1} \text{h}^{-1}$  (Figure 2b).

The  $\text{NO}_x$ –VOC sensitivity of  $\text{O}_3$  production for an individual plume determines both  $\text{O}_3$  production rates and response to the emissions from specific fires. A common tool used for understanding the nonlinear relationship between  $\text{O}_3$ ,  $\text{NO}_x$ , and VOC is the  $\text{O}_3$  isopleth. This analysis method has seen numerous applications to  $\text{O}_3$  sensitivities in urban areas,<sup>26,76</sup> oil- and gas-producing regions,<sup>28,77</sup> and  $\text{NO}_x$ -impacted, biogenic-rich environments,<sup>78</sup> but is less common in the analysis of fire plumes.<sup>39</sup> Fires differ from anthropogenic sources in two respects. First, BBVOC emissions differ markedly from urban or biogenic VOCs, with BBVOC reactivity dominated by species such as oxygenated and nonoxygenated aromatics, furans, and terpenes.<sup>22</sup> Second, BBNO $_x$  emissions vary and depend on both fuel nitrogen

**Figure 3.** Isopleths of maximum modeled  $O_3$  for two BB wildfire plumes utilizing a 0.5 FIRELAB VOC profile. Black dashed lines indicate maxima in  $NO_x$  sensitivity. (a) Modeled HK163 afternoon plume maximum  $O_3$  isopleth as a function of normalized  $NO_x$  and VOC base emissions. Each marker represents individual afternoon plumes in relative  $NO_x$ –VOC space, with error bars representing measurement error for  $NO_x$  (including HONO) and 50% error for VOCs (to encompass both VOC profiles). Below the isopleth shows cuts through the afternoon isopleth at the HK163 base case with normalized  $NO_x$  and VOC emissions of 1. (b) Modeled Cow 06 evening plume maximum  $O_3$  isopleth, as a function of normalized  $NO_x$  and VOC base emissions. Each marker represents evening plumes in relative  $NO_x$ –VOC space. Below the isopleth shows cuts through the evening isopleth at the Cow 06 base case with normalized  $NO_x$  and VOC emissions of 1.

content and fire stage (e.g., flaming or smoldering),<sup>20</sup> leading to potentially large variability in plume  $O_3$  production.

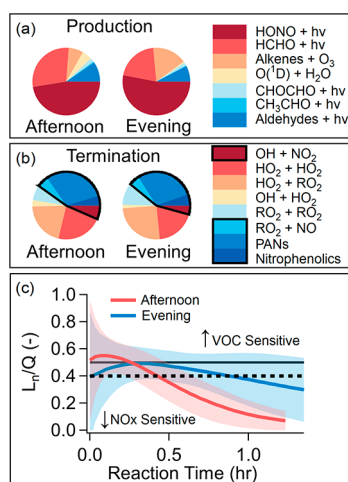

The HK163 and Cow 06 fires were chosen as base cases to represent the median  $NO_x$  and VOC emissions for afternoon and evening populations. Emissions in the model ( $NO_x$  + HONO and VOCs) are varied to determine the effect on  $O_3$  production in these BB plumes (for maximum  $O_3$  isopleths, see Figure 3). The relative VOC profile (including HCHO) for every model run was kept constant, which made it possible to plot all of the afternoon and evening fires on each isopleth, respectively. Both afternoon and evening fires fell in the VOC-sensitive regime of the maximum  $O_3$  isopleth, but were close to the  $NO_x$ -sensitive transition line (Figure 3). This result is surprising because fire emissions are expected to have high VOC and low  $NO_x$  emissions.<sup>17</sup> The modeled average initial VOC-to- $NO_x$  ratio (including HONO) was  $30 \pm 40$  and  $44 \pm 20$  ppbv C ppbv  $NO_x^{-1}$  for afternoon and evening plumes, respectively. In contrast, urban plumes as reported by Mao et al.<sup>34</sup> have generally lower average VOC-to- $NO_x$  ratios ( $24 \pm 10$  ppbv C ppbv  $NO_x^{-1}$ ).

**3.1. Modeled Radical Budget.** Maximum  $O_3$  isopleths describe only one point in a plume's chemical evolution. It is useful to investigate  $NO_x$ –VOC sensitivities as the plume advects downwind. The  $NO_x$ –VOC sensitivities of photochemical  $O_3$  production can also be expressed in terms of the sources and sinks of free radicals ( $HO_x + RO + RO_2$ ). The largest radical source in the lower atmosphere is the photolysis of  $O_3$  at wavelengths shorter than 340 nm, which yields excited oxygen atoms,  $O(^1D)$ , that react with water vapor to produce hydroxyl radicals.<sup>79</sup> Biomass burning, by contrast, directly emits photolytic radical precursors, such as HONO and HCHO. Photolysis of HONO, HCHO, other aldehydes, and acetone, along with the ozonolysis of alkenes,<sup>42,46,80</sup> leads to rapid  $HO_x$  production early in the evolution of fire plumes.

Large radical sources, in turn, tend to force  $O_3$  production into the  $NO_x$  sensitive regime.<sup>30,34</sup> While many of the same radical sources also influence urban air, they are not emitted at the concentrated levels found in early fire plume evolution. Peak actinic flux and FRP (proxy for emissions) both occur during the afternoon hours (Figure 1b), allowing for rapid  $HO_x$  production. During the evening hours, actinic flux decreases much more rapidly than FRP, reducing  $HO_x$  production and  $O_3$  production during potentially sustained emissions.

The afternoon plumes' primary  $HO_x$  ( $pHO_x$ ) budget was dominated by HONO photolysis, making up  $48 \pm 20\%$  (average  $\pm$  standard deviation) (Figure 4a). The second most important production term to the afternoon  $pHO_x$  budget was HCHO photolysis ( $26 \pm 9\%$ ); HCHO emissions were purely based on emissions databases; thus, the uncertainty with this radical source is high. The remainder of the  $pHO_x$  budget for afternoon plumes was made up of aldehyde photolysis, alkene ozonolysis, and  $O(^1D)$  ( $10 \pm 3$ ,  $7 \pm 5$ , and  $5 \pm 5\%$  respectively). The top three contributors to evening plumes'  $pHO_x$  budget were HONO photolysis ( $53 \pm 7\%$ ), HCHO photolysis ( $18 \pm 9\%$ ), and alkene ozonolysis ( $17 \pm 9\%$ ). The  $pHO_x$  budget for the FIRELAB emissions case differs markedly (Figure S7), with  $HO_x$  production in afternoon plumes led by HCHO photolysis ( $46 \pm 3\%$ ), alkene ozonolysis ( $16 \pm 3\%$ ), and HONO photolysis ( $13 \pm 4\%$ ).

In addition to these rapid primary  $HO_x$  sources, the rate at which radicals are terminated by  $NO_x$  is another critical aspect of  $O_3$  production efficiency.<sup>30</sup> Net  $O_3$  production from  $NO_x$  cycling between NO and  $NO_2$  is related to the coupled chain length of the  $HO_x$  cycle interconverting OH,  $HO_2$ , and  $RO_2$ . This chain propagation is characterized by the OH or  $HO_x$  chain length, with longer chain lengths resulting in more oxidative cycles per OH or  $HO_2$  radical, producing more  $O_3$ .<sup>34,81</sup> There are two channels of termination reactions, self-

**Figure 4.** Primary HO<sub>x</sub> (OH + HO<sub>2</sub>) production and radical termination budgets for the 0.5 FIRELAB VOC profile. (a) Average integrated afternoon and evening plume primary HO<sub>x</sub> production. (b) Average integrated afternoon and evening plume radical termination budgets, with  $L_n$  terms outlined in black. (c) Average afternoon and evening  $L_n/Q$  time series with one standard deviation shading and NO<sub>x</sub> sensitivity transition shown with black dashed trace ( $L_n/Q = 0.41$ ) and black solid trace ( $L_n/Q = 0.5$ ).

termination, where radicals react with themselves, and reactions of radicals with NO<sub>x</sub>, which remove both species from the propagation cycle. The formation of nitrophenolics is a chain termination reaction that is prevalent in BB plumes<sup>63</sup> but is minor in polluted urban areas.<sup>82</sup> Phenolic compounds are large BBVOC emissions whose oxidation to phenoxy radicals removes NO<sub>2</sub> from the system without producing O<sub>3</sub>.<sup>23</sup>

Integrated radical termination (Figure 4b) was split equally between radical loss to NO<sub>x</sub> and radical–radical reactions in both afternoon and evening plumes. In afternoon plumes, the radical loss to NO<sub>x</sub> was almost half ( $47 \pm 7\%$ ) of the termination budget compared to  $43 \pm 6\%$  for evening plumes, and in both afternoon and evening plumes, it was led by PAN formation ( $30 \pm 6$  and  $28 \pm 3\%$ , respectively). Plumes were sampled in an altitude range of 2200–4100 m and varied in temperature from 275 to 292 K, yielding thermal PAN lifetimes of 1.7–26 h, respectively. NO<sub>x</sub> termination products in these plumes are HNO<sub>3</sub> ( $7 \pm 1$  and  $4 \pm 2\%$  of the termination products for afternoon and evening, respectively), organic nitrates ( $6 \pm 1$  and  $5 \pm 1\%$ ), and nitrophenolics ( $5 \pm 2$  and  $6 \pm 5\%$ ). Nitrophenolics are considered permanent here in that their photolysis does not regenerate NO<sub>x</sub>, as has been suggested,<sup>83</sup> although nitrophenolic photochemistry requires further investigation. As the production of nitrophenolics was determined via the phenoxy radical + NO<sub>2</sub> pathway, this termination term includes both OH and NO<sub>3</sub> initiated H-atom abstraction.

The NOAA Twin Otter had limited observations of NO<sub>x</sub> oxidation products, mostly missing PAN. We present the available comparisons of modeled gas-phase HNO<sub>3</sub> to inorganic particulate nitrate (pNO<sub>3</sub>), modeled and measured gas-phase organic nitrates (C5 isoprene hydroxy nitrates), and modeled 4-nitrocatechol (4-NC) expected to be in the particulate phase ( $C^* \sim 14 \mu\text{g m}^{-3}$ ,  $78 \pm 10\%$  of 4-NC should be particle bound)<sup>63</sup> to a particulate nitrocatechol ion marker, pC<sub>6</sub>H<sub>5</sub>NO<sub>4</sub><sup>+</sup>, for a single flight in the Supporting

Information (Figure S8). The comparisons of HNO<sub>3</sub> with pNO<sub>3</sub> and between the C5 gas-phase nitrates are quite favorable, and both 4-NC and pC<sub>6</sub>H<sub>5</sub>NO<sub>4</sub><sup>+</sup> show similar trends with reaction time. However, the 4-NC comparison is not quantitative here because a calibration of particulate 4-NC with our AMS instrument is not available. Further work on the 4-NC comparison may highlight the uncertainty in the current understanding of nitrophenolic photolysis, as well as gas-phase and heterogeneous-uptake chemistry.<sup>83,84</sup>

The relative rates of radical production and termination provide a measure of the NO<sub>x</sub> sensitivity of O<sub>3</sub> formation that is independent of an isopleth calculation and can be evaluated instantaneously along a modeled plume's O<sub>3</sub> trajectory. The balance between radical production and termination at any point in the plume can be described by the parameter  $L_n/Q$ .<sup>27,30,85</sup>

$$L_n = P(\text{HNO}_3) + P(\text{RONO}_2) + P(\text{PAN}) + P(\text{nitrophenolics})$$

$$Q = L_r + L_n$$

The term  $L_n$  is the rate of radical (OH, RO, RO<sub>2</sub>) removal by reactions with NO<sub>x</sub>,  $L_r$  is the rate of self-radical removal (OH + HO<sub>2</sub>, RO<sub>2</sub> + RO<sub>2</sub>, etc.) and  $Q$  is the sum of all radical loss.<sup>27</sup> Classically, a plume is considered VOC-sensitive when the majority of radical termination proceeds via reactions with NO<sub>x</sub> or when  $L_n/Q > 0.5$ .<sup>27</sup> Additionally, a plume is NO<sub>x</sub>-sensitive when  $L_n/Q < 0.5$  or when radical–radical reactions govern radical chain termination.<sup>27</sup> However, when additional  $L_n$  terms are added to the analysis (such as PAN or nitrophenolics), the transition from VOC- to NO<sub>x</sub>-sensitive chemistry can differ from the classical definition.<sup>86</sup> An analysis of both afternoon and evening isopleths yield an  $L_n/Q$  transition of 0.41 for BB chemistry (Figures S9 and S10). As evidenced by their  $L_n/Q$  time series, afternoon plumes transitioned from near-maximum NO<sub>x</sub> efficiency to NO<sub>x</sub>-sensitive chemistry downwind, on average after 26 min of photochemistry (Figure 4c). Not only was the transition rapid, but after 1.25 h of photochemistry, modeled  $L_n/Q$  values for afternoon plumes reached  $0.07 \pm 0.1$ , or strongly NO<sub>x</sub>-sensitive. Meanwhile, evening plumes remained close to maximum NO<sub>x</sub> efficiency for the duration of this analysis (Figure 4c) with a maximum in  $L_n/Q$  after 22 min of photochemistry. Thus, evening plumes demonstrated a slower transition to NO<sub>x</sub>-sensitive O<sub>3</sub> production than afternoon plumes. The evening transition to NO<sub>x</sub>-sensitive O<sub>3</sub> production was less drastic than in the afternoon plumes, with average  $L_n/Q$  values at 1.25 h of  $0.29 \pm 0.2$ .

This study emphasizes the importance of time-of-day parameterization of BB plume O<sub>3</sub> production in chemical models. Afternoon plumes demonstrated a rapid transition to NO<sub>x</sub>-sensitive O<sub>3</sub> production and sequestered NO<sub>x</sub> in the form of PANs, organic nitrates, HNO<sub>3</sub>, and nitrophenolic compounds. Interestingly, PAN formation is quite similar for both VOC profiles. The similarity may be due to substantial secondary acetaldehyde production (compensating for differences in initial VOC emissions) or differences in initial NO<sub>2</sub> emissions for each VOC profile. As a fire emits into the evening hours, reduction of photolysis rates and emissions of radical precursors limit the production of primary radicals, slowing the transition to NO<sub>x</sub>-sensitive chemistry. Fire plumes much larger than those sampled by the NOAA Twin Otter may exhibit aspects of evening plume chemistry due to large

reductions in photolysis rates. Further validations of the NOAA BB chemical mechanism for NO<sub>x</sub> oxidation products (i.e., organic nitrates, nitrophenolics) and loss mechanisms will be important to improving chemical models of BB plumes. Due to the near-field (<2 h) focus of this analysis, an important extension of this work is to understand how BB plumes interact with urban NO<sub>x</sub> and radical sources many hours downwind. The NO<sub>x</sub> sensitivity in even moderately aged plumes suggests the potential for efficient O<sub>3</sub> production through interactions with urban emissions.
