RESEARCH REPORTING SERIES

Research reports of the Office of Research and Development, U.S. Environmental Protection Agency, have been grouped into nine series. These nine broad categories were established to facilitate further development and application of environmental technology. Elimination of traditional grouping was consciously planned to foster technology transfer and a maximum interface in related fields. The nine series are:

1. Environmental Health Effects Research
2. Environmental Protection Technology
3. Ecological Research
4. Environmental Monitoring
5. Socioeconomic Environmental Studies
6. Scientific and Technical Assessment Reports (STAR)
7. Interagency Energy-Environment Research and Development
8. "Special" Reports
9. Miscellaneous Reports

This report has been assigned to the INTERAGENCY ENERGY-ENVIRONMENT RESEARCH AND DEVELOPMENT series. Reports in this series result from the effort funded under the 17-agency Federal Energy/Environment Research and Development Program. These studies relate to EPA's mission to protect the public health and welfare from adverse effects of pollutants associated with energy systems. The goal of the Program is to assure the rapid development of domestic energy supplies in an environmentally-compatible manner by providing the necessary environmental data and control technology. Investigations include analyses of the transport of energy-related pollutants and their health and ecological effects; assessments of, and development of, control technologies for energy systems; and integrated assessments of a wide range of energy-related environmental issues.

EPA REVIEW NOTICE

This report has been reviewed by the participating Federal Agencies, and approved for publication. Approval does not signify that the contents necessarily reflect the views and policies of the Government, nor does mention of trade names or commercial products constitute endorsement or recommendation for use.

This document is available to the public through the National Technical Information Service, Springfield, Virginia 22161.

Washington, DC 20460

ABSTRACT

This study provides information about emissions from waste crankcase oil heaters. The data provided should be useful to heater manufacturers and to regulators. Burner design and fuel composition both have an obvious effect on the level of inorganic elements emitted. The vaporizing pot burner retained a significant amount of the trace elements to be carried by the flue gas into the stack. The study also showed that total organic emissions from the two burner designs are similar. However, higher levels of polynuclear aromatic hydrocarbons (PAH) were found in discharges of the vaporizing pot burner.

ACKNOWLEDGEMENTS

We are especially grateful to Robert E. Hall, EPA Project Officer, whose invaluable guidance during the study is greatly appreciated; and to Richard Perry, EPA/RTP, for his indispensible contribution to the preparation of sampling data.

The following Battelle-Columbus Laboratories staff are noted for their technical assistance and cooperation in completing this task:

Thomas Danison for the TCO analyses; Marvin Miller and Paula Chinn for the ICAP analyses; Mary Ann Roe for the extractions, gravimetric analyses and coordination of sample distribution and collection of resulting data; Phil Schumacher for the Spark Source analysis; and Richard Thompson for the LRMS analyses and interpretation.

The helpful advice of Bruce Rising, Battelle-Columbus, is also appreciated. Bruce gave generously of his time and helped correlate measured emissions with the combustion processes involved.

SECTION 1

INTRODUCTION

Emissions from two waste oil fired space heaters were sampled by the EPA and chemically analyzed by Battelle-Columbus Laboratories using EPA Level 1 procedures (1), together with advanced metals analysis. A vaporizing heater system (Kroll Waste Oil Heater) which operates by vaporizing the oil for combustion was used for one set of studies. The second heater was an air atomizing unit which atomizes oil into the combustion zone (Dravo/ Hastings Thermoflo Waste Oil Heater). The different oil induction systems result in differences in the kind and amount of sample recovered from the units. The vaporizing pot heater produced both flue gas and a pot residue, whereas, the air atomizing heater produced only flue gas. The combustion of both truck and automotive crankcase oils was examined in each heater, resulting in four test runs. During each of these four test runs, the stack was sampled by two different techniques: the Source Assessment Sampling System (SASS) train and a dilution tunnel, thus producing eight sets of sampling data. Specifically, the following analyses were performed:

1. Level 1 analysis of four SASS trains, four sets of dilution filters and two samples of pot residue.

2. Determination of heating value, moisture, ash, viscosity, and C, H, N, S, analysis of the two waste oils.

3. Inductively coupled argon plasma (ICAP) analysis for 28 elements on 20 samples to include:

    4 - combined particulates from SASS trains

    4 - combined 1st impinger and module condensate solutions

    4 - 2nd and 3rd impinger solutions

    4 - dilution filters

    2 - pot residues

    2 - waste crankcase oils

The two burners tested are illustrated in Figure 1.

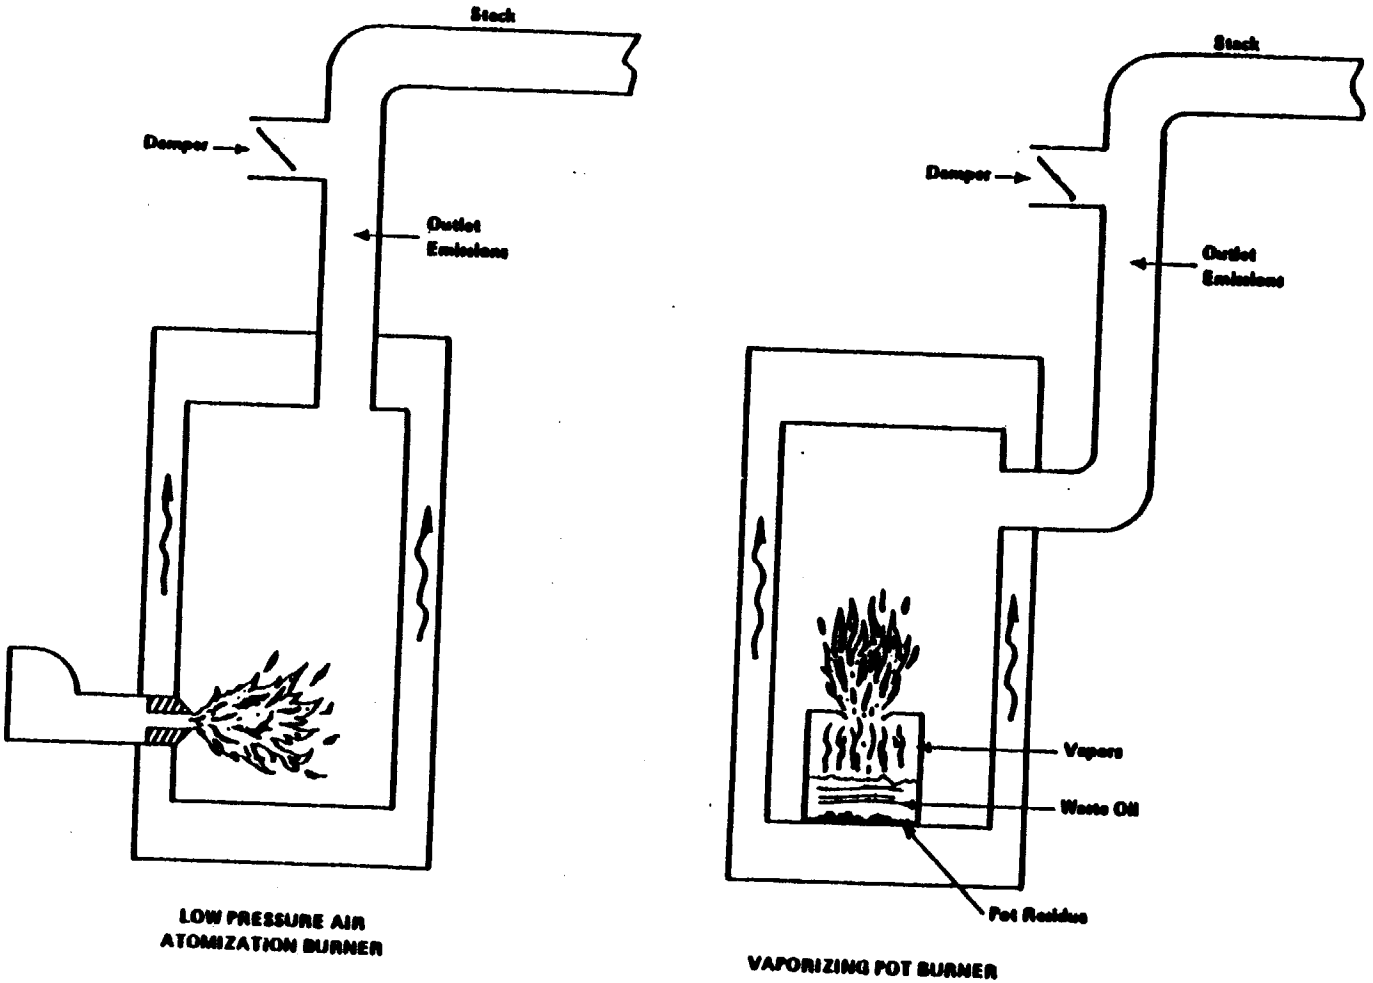

FIGURE 1. LOW PRESSURE ATOMIZING AND VAPORIZING POT COMBUSTION PRINCIPLES.

SECTION 2

CONCLUSIONS

Three basic comparisons were performed in this study: burner type, fuel, and method of sample collection. Two types of space heaters were studied; low pressure air atomization and vaporizing pot. Both heaters are designed to operate on waste engine oil. Two fuel types were compared in this study; one fuel obtained from an automotive, waste oil supplier, and a second fuel which primarily contained engine oil used for truck lubrication.

The sampling comparison was made between two methods used to collect gaseous emissions. One technique, the Source Assessment Sampling System (SASS), provides information about the size distribution of particulate discharges in burner outlet gas streams. The SASS sampler is also efficient for collecting gaseous discharges, principally organic material, which is collected by sorption on a resin bed. The second sample collection system, a dilution tunnel, employs a clean air dilution stream followed by filtration. By diluting the hot discharge gases before a sample is collected, the dilution tunnel theoretically simulates the natural dilution and chemical transformation that occurs when stack gases are discharged to the atmosphere.

The dilution tunnel method is designed to collect particulate matter, including organic materials. The large gas volumes involved in the dilution tunnel prohibit collecting vapors. In this system, the gas sample is introduced into a cylindrical dilution chamber in which the gas is mixed with filtered dilution air which has been passed through a laminar flow element. The resulting mixture is trapped by filtration at the end of the dilution tunnel where a 20 inch square Teflon-coated fiberglass filter collects the sample. Dilution ratios of 10:1 were used. Laboratory experiments have shown that thorough mixing occurs, and that condensation aerosols are formed in the dilution chamber.

The obvious difference between burner types is the residue produced by the vaporizing pot burner. The air atomizing burner yielded higher gas-phase concentrations of most inorganic species than the vaporizing pot combustion system. In both combustion systems, the time-weighted-average threshold limit values (TLVs) were exceeded for several elemental species. The vaporizing pot burner produced lower trace specie air emissions, because a significant amount was retained in the pot residue.

No firm health risk conclusions can be drawn directly from the results of this project. Stack concentrations were sampled, not ground level ambient concentrations. Although the dilution tunnel theoretically simulates natural dispersion and dilution, it is not certain at this time whether the tunnel accurately simulates air circulation in and around a service station or garage workplace, where these heaters are commonly used.

Two fuel types were compared in this study: one was an automotive crankcase waste oil obtained from a service station, and the second fuel was a truck crankcase waste oil that came from a diesel truck fleet. Fuel comparisons revealed generally higher concentrations of metallic species in the automotive oil. Total organic concentrations were relatively similar for the two fuels although chemical composition of the organic discharges were different.

It was apparent in these tests that the dilution tunnel did not efficiently collect the gaseous discharges measured. A dilution tunnel is expected to lose volatile and semivolatile organic species.

Specific correlations derived from the study given in the following summary.

AIR ATOMIZING VERSUS VAPORIZING POT HEATERS

- Polynuclear Aromatic Hydrocarbons (PAH) were identified in emissions from the vaporizing pot burner. The highest levels of PAH were found in pot residues when automotive crankcase oil was used as the fuel; however, PAH were also found in the gaseous emissions from vaporizing pot tests using truck waste oil.

- Total organics emitted from these heaters were similar in quantity and type. However, the vaporizing pot heater showed significant quantities of organic material in the pot residue, indicating that the air atomizing heater produces less overall organic material than the vaporizing pot and is therefore burning more efficiently.

- The vaporizing pot heater, which burns heated oil vapor, produces a pot residue. The air atomizing heater which atomizes the fuel before combustion, does not produce a pot residue but does produce a coating of particulate on the surface of the combustion chamber and heat transfer surfaces. It was observed that the air atomizing heater releases much higher concentrations of metals into the air than does the vaporizing pot. This trend is not followed by the organics as mentioned above.

- Mass balances of elements present in the fuel and the effluents were better for the vaporizing pot than for the air atomizing heaters.

SASS TRAIN VERSUS DILUTION TUNNEL SAMPLING

- The SASS train collected more organic material than the dilution tunnel. Three of the four tests showed 20-30% lower organic concentration when sampled by dilution tunnel.

- The SASS train was found to collect a higher percentage of the metals present in the fuel than the dilution tunnels.

TRUCK VERSUS AUTOMOTIVE CRANKCASE OILS

- Ultimate analysis of the two fuels indicated a higher oxygen content in the automotive crankcase oils. What effects, if any, this had on combustion or combustion products is unknown.

- The automotive waste crankcase oil contained a higher concentration of metals than did the truck crankcase oil. This was reflected in the effluents.

SECTION 3

EXPERIMENTAL

A modified Level 1 (1) analysis of four crankcase oil effluents was performed. The specific methods and approach are described below.

SAMPLING

EPA personnel at Research Triangle Park sampled effluents from two space heaters burning waste crankcase oils. The vaporizing pot unit was initially fired with 250 ml of #2 fuel oil to bring the temperature to a sufficient level for the vaporization of the waste oils tested. Then sufficient waste oil was combusted to operate the unit for the approximately five hour sampling run. A portion of the waste oil not vaporized remained as a residue in the vaporizing pot, and it too was analyzed. The second heater utilized an air atomizing burner. This unit did not produce sufficient residues to be analyzed although a light deposit was found in the combustion chamber and heat exchanger.

Two sampling runs were performed on each heater, one burning waste crankcase oil from automotive engines, and one burning waste crankcase oil from truck engines, for a total of four sampling runs. The two fuels were waste crankcase oils recovered from the crankcase of trucks burning diesel fuel, herein referred to as "truck", and from motor vehicles burning gasoline, herein referred to as "automotive". No distinction other than fuel burned by the vehicle was made when waste crankcase oils were collected. Each effluent was sampled using a Source Assessment Sampling System (SASS) train and a dilution tunnel. Samples received by Battelle, their identification number, and analyses performed are summarized in Tables 1 through 4.

FUEL ANALYSIS

Phoenix Laboratories (Chicago, Illinois) performed the analyses on both the truck and automotive crankcase oils. These analyses included heat value, density, moisture, ash, and elemental analysis for C, H, N, and S. ICAP (inductively coupled argon plasma) analysis was done on each fuel to determine 28 elements, as well as AAS (atomic absorption spectrometry) for mercury, arsenic, and antimony determinations.

ORGANIC ANALYSIS

Samples were received and extracted with methylene chloride for 24 hours in preparation for organic analysis. Samples extracted included SASS particulate filters, probe rinse, XAD-2 sorbent, module condensate and filter

samples from the dilution tunnel, hereafter called "dilution filters". Also extracted was the 3-10 μm particulate catch from the air atomizing heater tests; however, there was insufficient cyclone material from the vaporizing pot heater tests to perform any organic analyses. On all extracts, total chromatographic organics (TCO) and gravimetric (GRAV) analyses were performed to establish total organic content, and infrared (IR) spectra were obtained to determine organic functional groups. The only exception to the above are the SASS particulate filters and probe rinses which did not receive TCO analysis since the temperature at which they were sampled precluded the presence of volatile materials.

Any sample containing 15 mg or more of available organic material (that is, 15 mg excluding material already used in the TCO, GRAV, and IR procedures) was separated by liquid chromatography (LC) into seven fractions of increasing polarity. Each LC fraction was then analyzed by TCO, GRAV, and IR. In addition, any fraction or combination of two fractions (2 & 3, 4 & 5, and 6 & 7) which contained 0.5 mg/m^3 organic material at the source was analyzed by low resolution mass spectrometry (LRMS). As previously mentioned, specific analyses performed on each sample are delineated in Tables 1 through 4.

INORGANIC ANALYSIS

The analysis included: spark source mass spectroscopy (SSMS) using an AEI Model MS-702R instrument to screen elemental constituents; inductively coupled argon plasma (ICAP) spectrometry using a Jarrell-Ash Model 975 instrument to analyze elemental species; atomic absorption spectroscopy (AAS) using a Perkin-Elmer Model 5000 instrument to provide mercury (Hg), arsenic (As), and antimony (Sb) emissions data.

Samples, analyzed by spark source mass spectrometry (SSMS) (74 elements) and atomic absorption spectrometry (AAS) (for mercury), were the SASS particulate filters, probe rinses, XAD-2 sorbents, combined module condensate and 1st impinger solutions, pot residues, 3-10 μm particulate catch (except the vaporizing pot/automotive test) and dilution filters. The vaporizing pot/automotive test did not generate any 3-10 μm particulate. Mercury, antimony, and arsenic were determined by AAS in the combined 2nd and 3rd impinger solutions, pot residues, both fuels and for two samples from corrosion of the dilution tunnel inlet tube. The latter two samples were a scraping from the inner surface of the dilution tunnel inlet tube and a nitric acid rinse of this same surface. These were taken to clarify if corrosion of the inlet tube could contribute to the composition of the effluent when sampled by the dilution tunnel. Appropriate blanks were run for all analyses.

Inductively coupled argon plasma (ICAP) for more precise analysis of elemental species (a Level II procedure) was specified by the EPA project officer on selected samples: the fuel oils, combined SASS particulate samples, 1st impinger solution combined with the module condensate, pot residues, combined 2nd and 3rd impinger solutions, and the dilution filters. No sample blanks were analyzed by ICAP. The ICAP instrument used for these analyses was configured for the determination of 30 elements. Analyses were conducted for 28 elements, excluding mercury and bismuth.

SECTION 4

RESULTS AND DISCUSSION

Results are compiled under three major areas: stack sampling techniques, chemical and physical analyses of the fuels, and chemical analysis of the effluents. Each area is treated separately.

SAMPLING

Sampling data pertinent to this report are summarized in Table 5. SASS trains sampled approximately 30 m^3 of each effluent with the exception of the air atomizing heater burning automotive crankcase oil (air atomizer/automotive) from which only 15.4 m^3 were sampled due to problems with air feed through the particulate filter. Larger sample volumes were collected in the dilution tunnel samples ranging from 80 m^3 for the vaporizer/truck to 126 m^3 for the vaporizer/automotive test.

The volumetric flow rate, Q, in m^3/sec was calculated using the fuel feed rate and the physical characteristics of the two fuels. The calculation used is given in Appendix C. Q was also calculated from the Alnor velometer reading. This value was not used in further calculations for this report as the Alnor can have a variance of 13% at the stack temperature used. However, Qs derived by the two methods agreed within 10%. All flow rates were very low.

FUEL ANALYSIS

Results of the fuel ultimate and proximate analyses are given in Table 6. Heating values for both truck and automotive crankcase oils are similar to those expected for a #2 fuel oil. Both oils are quite viscous (having high resistance to flow, approximately a factor of 30 more viscous than #2 fuel oil) and have relatively high values for water (by the Karl Fischer method), ash, and sulfur; however, these are all expected in waste oils. The automotive waste oil had a lower carbon value (81.30%) as well as a higher hydrogen/carbon ratio than is expected for engine oils. Because of the unusual nature of this finding, the carbon determination was repeated and found to be correct.

Comparisons with literature (2) for density, heating value and hydrogen/carbon ratios suggests that these two waste oils are similar to #4 fuel oil in their combustion properties.

Both crankcase oils were also analyzed by ICAP and AAS to determine fuel elemental mass values for calculating the mass balance of elemental species

in the fuels and emissions. The automotive crankcase oil contained much higher concentrations of metals than did the truck. Results are further discussed in the section containing inorganic analyses.

ORGANIC ANALYSIS

These emissions had relatively low organic loadings (just over 1 mg/m^3 at the source) and a chemical composition generally showing normal combustion products. This organic loading is less than conventional oil combustion in home units and less than effluents from coal combustion. The pot residue of the vaporizing heater is considered separately from the stack effluents.

Organic Loading

Organic loading as indicated by the SASS train samples was similar for all four test runs (see Figure 2) with the concentrations being slightly lower when burning automotive crankcase oil than with truck crankcase oil. For all tests, excluding the air atomizing/automotive test, dilution tunnel sampling indicated 20 to 30% less organic material than did the SASS train (see Figure 3). Both sampling methods indicated essentially the same concentration of organics in the air atomizing/automotive test. This test also had the lowest total organics of the four test runs as seen by the SASS train, and was the test in which only 15 m^3 were sampled by the SASS train. Both of these latter two conditions could effect the relative quantities of organics collected by the two sampling methods.

Although the pot residue from the vaporizing heater does contain significant concentrations of organics, this apparently does not diminish the organics in the stack, indicating that overall, the efficiency of the vaporizing heater is less than that of the air atomizing heater. Vaporizing burner/automotive pot residue had a much greater concentration of organics than the vaporizing burner/truck pot residue (601 mg/kg versus 61 mg/kg).

Because of the low organic loading, only 8 samples met the criterion of 15 mg required for liquid chromatography (LC) analysis. These were all the dilution filters, all of the XAD-2 sorbent modules (except from the air atomizing burner/automotive) and the pot residue from the vaporizing burner/automotive. After liquid chromatography, only 11 individual fractions (or combinations of two fractions) indicated sufficient concentration ($\geq$0.5 mg/m^3 at the source) to require low resolution mass spectrometry (LRMS). Samples subjected to liquid chromatography and LRMS are summarized in Table 7.

Organic Composition

The organic data are summarized in Tables 8-12. All organic data, including organic summary tables, are in Appendix A.

The chemical composition of the organic portion of the samples from all four effluents, sampled by both SASS train and dilution tunnel, was generally similar. The two major types of constituents were hydrocarbons (mainly aliphatic, some olefinic and aromatic); and oxidized species such as ketones

esters,aldehydes, acids, and to a lesser extent, ethers, anhydrides, alcohols, and lactones. One compound type of an unusual nature and of possible significance from a health standpoint was a primary amine salt found in the sorbent column of the air atomizing burner/truck. PAH was found in the pot residue of the vaporizing burner/automotive and in the sorbent column from the vaporizing burner/truck tests. Because the PAH found in the pot residue does not enter the stack and therefore does not enter the air, it is only relevant to disposal of the pot residues. However, the PAH found in the sorbent column of the SASS train from the vaporizing burner/ truck test could be significant. It should be considered that infrared analysis did indicate the presence of aromatic ring compounds in many of the samples including LC Fractions 2 and 3 of most of the liquid chromatographed samples. This finding indicates that PAHs and related compounds could be present, although in very low concentrations confirmed by EPA spot test results. Specific differences are looked at comparing the three major test parameters: air atomizing versus vaporizing heaters, truck versus automotive crankcase oils, and SASS train versus dilution tunnel sampling.

Air Atomizing Versus Vaporizing Heaters--

Some differences in organic composition were noted in comparing the two heater types. Alkyl benzenes were found only in air atomizing effluents. Benzoic acid was identified in two of the samples, however, benzoic acid is identified only after liquid chromatographic separation. Since this separation was not performed on the XAD-2 blank in this study, benzoic acid was not specifically identified in this blank. Therefore it is unknown what concentration of carboxylic acid present in the XAD-2 extract is coming from the stack as opposed to an extraction product of the XAD-2 itself.

Fraction 3 of the XAD-2 extract for the vaporizing burner truck test showed significant concentrations of organic materials. No other Fraction 3 for any other test contained similar quantities. Because Fraction 3 may contain PAH, a mass spectral analysis was performed to confirm or deny the presence of PAH. Results showed that the majority of material in this fraction was indeed PAH. Thus, the vaporizing burner truck test was the only test showing PAH in the gaseous effluent. This does not negate the fact that in in the pot residues, the vaporizing burner automotive test showed far more PAH than did the truck test.

Truck Versus Automotive Crankcase Oils--

Two compound types were seen in considerably higher concentrations in the truck than in the automotive effluents. These were acid salts and lactones, both highly oxidized species. Ethers were more commonly identified in the automotive samples than in the truck samples.

SASS Train Versus Dilution Tunnel Sampling--

As previously mentioned, for the automotive samples, much less aliphatic hydrocarbon is collected by dilution tunnel than by SASS train sampling, indicating the possibility of chemical transformation of sampling losses. Higher concentrations of esters were collected by SASS train than by dilution tunnel,especially for air atomizer/automotive which had 1.10 mg/m^3 by SASS train compared to 0.04 mg/m^3 by dilution tunnel. In fact, this SASS train value was significantly higher than any other of the ester concentrations.

The SASS trains also collected more alcohols than the dilution tunnels. Benzoic acid was found only in SASS train samples (see previous discussion).

Vaporizing Burner Pot Residues--

Comparison of the two pot residues is complicated by the fact that the vaporizing/automotive sample had significant sample for LC whereas the vaporizing/truck sample did not. For both pot residues, the major constituent is aliphatic hydrocarbons. Vaporizing/automotive also has high concentrations of olefinic and aromatic hydrocarbons, including PAHs. The vaporizing/truck appears to have a relatively higher concentration of oxidized species including esters, ketones, and lactones. It is important to again note that whatever the concentration of organics in the pot residue, it does not affect the concentration of organics in the stack.

INORGANIC ANALYSIS

Atomic absorption spectrometry (AAS) and spark source mass spectrometry (SSMS) are the two methods specified by EPA Level 1 guidelines (1) for analysis of inorganics. AAS was used to determine mercury, antimony, and arsenic. SSMS is the method which Level 1 guidelines specify for the determination of elements other than mercury, arsenic, and antimony. SSMS is useful for the determination of a majority of elements (71) in a single analysis and thus is inexpensive on a per element basis.

Analytical Accuracy

The trade-off in using SSMS, which is a rapid, inexpensive, and comprehensive method, is a less than optimum accuracy and precision. Work done for the Department of Energy by Battelle (Contract No. AC01-77ET10386) entitled, "Emissions and Efficiency Performance of Industrial Coal Stoker Fired Boilers" included a study of the reproducibility of SSMS data. Five replicate runs were made and relative standard deviations computed for 59 elements. The majority of elements (65%) had relative standard deviations (RSDs) between 31 and 70%. Ten percent had RSDs greater than 70% and 25% had RSDs equal to or less than 30%.

Inductively coupled argon plasma (ICAP) is a relatively new method by which multielement analysis can be done (3). At Battelle, ICAP is currently configured to analyze for 28 elements. Many of the samples from these tests were analyzed by both SSMS and ICAP for comparison. A study similar to that described for SSMS was done for 23 elements by ICAP (EPA Contract No. 68-03-2552; "Development of a Methodology for the Evaluation of Solid Waste"). In this case, 66% of these elements showed RSDs of 1-5%. Seventeen percent had RSDs of less than 1% and 17% had RSDs greater than 5%.

Atomic Absorption Spectrometry

AAS results are summarized in Tables 13-16. Antimony was neither detected in any of the four effluents nor in either fuel. However, low concentrations were found in both pot residues: 6 µg/g in the test burning truck crankcase oil and 26 µg/g in the test burning automotive crankcase oil. The source of this antimony is unknown.

Arsenic was detected in both fuels: 0.3 μg/g in the truck and 0.6 μg/g in the automotive. For the vaporizing burner, arsenic was detected in both pot residues although in low concentration. Arsenic was not detected at all in the vaporizing burner/truck effluent and at a very low level (0.05 $\mu g/m^3$) in the vaporizing burner/automotive effluent. However, arsenic was detected in higher concentrations for the air atomizing heater: 0.25 $\mu g/m^3$ when burning automotive fuel and 0.32 $\mu g/m^3$ when burning truck fuel. These are still well below the threshold limit value of 200 $\mu g/m^3$ established for arsenic. This disproportion of arsenic from the two heaters actually is part of a trend: metals were generally present in greater concentration in the air atomizing stack. This result was expected since the air atomizing heater atomizes the fuel before combustion and no pot residue is produced.

All of the effluents and the pot residues indicate very low levels of mercury. This is interesting in view of the fact that neither fuel contains any mercury. However, several blanks (2nd and 3rd impingers, XAD-2, and dilution filter) do contain mercury, although the blank value is subtracted before reporting sample values. Also, there is some mercury in the scraping from the dilution tunnel inlet tubes. Since all values are well below the threshold limit value of 50 $\mu g/m^3$ the levels of mercury are not of paramount interest. Nonetheless the origin of mercury in both the blanks and stack effluent is unknown.

Spark Source Mass Spectrometry

SSMS data are given in Appendix B. Metals for all runs were quite high; due to its design, the air atomizing heater causes more of the trace metals to be discharged from the stack than the vaporizing heater. This is logical since many metals remained in the pot residue of the vaporizing heater. One problem arose concerning SSMS. Due to an instrument malfunction, beryllium could not be detected by SSMS. Correcting this malfunction would have entailed a significant delay. ICAP, however, was also used to analyze beryllium and none was detected in any of the samples. This was discussed with the EPA Project Officer and it was decided to proceed without beryllium determination by SSMS. Further details concerning concentrations of specific elements are given in the section comparing SSMS and ICAP.

Inductively Coupled Argon Plasma

ICAP data are given in Appendix B. Results by ICAP for each SASS train, dilution tunnel and fuel were calculated relative to quantity of fuel burned. That is,

$$\frac{\text{total quantity of element detected } (\mu g)}{\text{total quantity of fuel burned } (g)}$$

These are graphically illustrated in Figures 4 through 13 (numerical values used to generate these Figures are given in Appendix B). This elemental mass balance was done using ICAP only, since the fuels were analyzed by ICAP and not by SSMS, and since ICAP is much more precise than SSMS.

Figures 3 through 5 show mass balances for the vaporizing heater fuels and pot residues (figure 5 includes elements from both test runs). Figures 6 and 7 show comparable data from the SASS trains and dilution tunnels. Two generalities can be made for the vaporizing heater:

1. Most of the metals from the fuel are retained in the pot residues rather than emitted from the stack.

2. More metals are collected by the SASS train than by the dilution tunnel.

For the vaporizing heater burning either fuel there are a few elements in both the pot residue and the SASS train samples which either are not in the fuel at all, or which exceed the quantity found in the fuel. There are three elements found in the SASS train samples which exceed significantly that found in the fuel; these are chromium, iron and nickel. Since these elements are 1) components of steel, 2)exceed fuel values only in the SASS train samples and 3)the SASS train is constructed of stainless steel, it is suspected that these three elements are being leached from the SASS train itself.

Figures 9 through 13 show mass balance data for fuels, SASS train and dilution tunnel samples from the air atomizing heater tests. The trend of greater mass collection by SASS train than by dilution tunnel is also seen in the mass balances for the air atomizing heater. For this heater, the total amount of each element detected is measured in the stack, since the air atomizing heater does not produce a pot residue. Not surprisingly, the concentrations of metals being emitted from the stack are much greater for this heater than for the vaporizing heater. Again, a few elements were detected in the effluent by both SASS train and dilution tunnel sampling which were not detected in the fuel. Also a very few exceeded quantities found in the fuel. However, the levels of iron, nickel and chromium do not exceed quantities in the fuel for the SASS train as seen within the vaporizing heater. This is probably because a much higher concentration of iron is being emitted from the air atomizing heater stack than from the vaporizing heater stack (due to methods of combustion) so that any possible leaching of the SASS train is not significant compared to stack effluent concentrations.

There was a suspicion that corrosion of the dilution tunnel inlet tube could be contributing to effluent concentrations of some elements. Table 17 shows the results of ICAP on both scrapings of the corrosion product itself and a nitric acid rinse of the corroded area. There is no indication that any of these elements are being leached into the dilution tunnel sample. However, there is a surprisingly high concentration of lead in these samples: 1850 µg/g in the scrapings and 16,000 µg/g in the nitric acid rinse. In addition, concentrations of lead indicated by dilution tunnel sampling are significantly lower than those indicated by the SASS train for all four test runs. This implies that some of the lead from the effluent is being deposited onto the dilution tunnel inlet tube.

Considering the variety of matrices requiring analysis (fuel, impingers, bottom ash, filters), the overall agreement shown in Figures 3 through 12 is excellent for most elements, and indicates the accuracy and precision available with ICAP. Mass balances are somewhat better for the vaporizing heater than for the air atomizing heaters apparently because the majority of metals are in the pot residue.

IR ANALYSIS REPORT

Contractor Battelle Columbus Laboratories

Type of Source Vaporizing pot/automotive

Test Number E0502081 **Sample ID Number** KEA-BCL-PFa5-E052081/ KEA-BCL-PFa6-E052081

Sample Description Particulate filters # 5 and 6 combined

Responsible Analyst Rachael L. Barbour **Date Analyzed** 6-10-81

Calculations and Report Reviewed By Robert J. Jakobsen **Report Date** 7-31-81

Instrument Digilab FTS-10 **Sample Cell Type** Film on KBr Plate

Utilized Max/Min Signal Intensity Values

Observations

Mostly aliphatic hydrocarbon with some carbonyl structure, probably ester and ketone. Very small amounts of aromaticity. Not much sample present.

Comparison of ICAP and SSMS

A total of 14 samples were analyzed by both methods including dilution filters, SASS particulate filters, combined 1st impinger and condensate solutions. For the most part, agreement was good; any concentration within a factor of three was considered to be equal. A factor of three was chosen because with only one data point for each value, the following had to be taken into account:

(1) possible non-homogeneity of sample,

(2) the 30-70% relative standard deviation of SSMS, and

(3) possible interferences.

For both ICAP and SSMS, interferences will usually enhance the signal although an iron interference (high for most of these samples) can generate low values by ICAP for some elements. Non-agreement generally did not show any pattern: sometimes ICAP was lower, sometimes SSMS was lower and disagreement of greater than a factor of three were found to occur at least once in 21 of 28 elements. There were four elements which did not match at least half the time: boron, lead, titanium, and calcium. Boron was higher in all samples by ICAP. This is expected because samples are subjected to an acid digestion in a glass vessel before ICAP. During this digestion, boron may be leached from the glass. The other three elements showing a high incidence of non-agreement also are consistently analyzed in higher concentration by either ICAP or SSMS as shown in Table 18.

TABLE 18. ELEMENTS WITH CONFLICTING SSMS AND ICAP CONCENTRATIONS

Element	Method of Highest Concentration	Occurance
Calcium	ICAP	12 of 14 analyses
Lead	ICAP	10 of 14 analyses
Titanium	SSMS	13 of 14 analyses

TLVs are issued and updated by the American Conference of Governmental Industrial Hygienists (ACGIH). These values refer to airborne concentrations and represent the maximum level that will allow repeated worker exposure, in this case for an 8 hour work day, without adverse effects. TLVs are based on the best available information from industrial experience, from experimental human and animal studies, and, where possible, from combinations of the three. The TLVs are generally species specific, in other words, zinc

standards are specific to zinc chloride fume, zinc chromate, and zinc oxide fume. This implies a knowledge of speciation in order to make direct comparisons with emitted elements in the combustion gases.

TLVs could be useful in estimating potential health impacts from waste oil combustion since the operation of these devices often corresponds to a normal work day. However, it should be noted that most garages (where these heaters are often used) are open more than 8 hours a day, and usually six days a week. A better evaluation of human health risk would require advanced speciation of both organic and inorganic species generated in waste oil combustion, Level 2 testing and ground level modeling to show the direct human exposures.

Nine elements exceed TLVs as assigned by the ACGIH as indicated by both SSMS and ICAP data. These were cadmium, chromium, cobalt, copper, iron, lead, nickel, phosphorus, and zinc. Their concentrations are given in Table 19. Table 20 shows the specific species for which the TLVs were derived. It is important to note that TLVs have not been established for elemental species thus gas discharge concentrations and TLVs cannot be directly compared. Both SASS train and dilution tunnel samples again show generally higher metals emission by the air atomizing heater than by the vaporizing heater. For the most part, the air atomizing heater, when burning either fuel, exceeded the TLVs when sampled by the SASS train. The only real exception is cobalt in the air atomizing/truck test. Cobalt and cadmium in the air atomizing/automotive test and cadmium in the air atomizing/truck test exceed the TLVs when analyzed by ICAP but not by SSMS. Conversely, chromium in the air atomizing/truck test exceeded the TLV when analyzed by SSMS but not by ICAP. Fewer elements exceeded the TLVs when collected by dilution tunnel. This is because generally lower concentrations of all elements were collected by the dilution tunnel than by the SASS train.

As mentioned before, element stack emission values for the vaporizing burner were usually lower than those for the atomizing burner. For the SASS train samples collected while burning both truck and automotive fuel, five elements exceeded the TLV (either as indicated by SSMS, ICAP, or both). These were lead, chromium, nickel, iron, and cobalt. However, dilution tunnel samples showed only lead in the automotive test to exceed the TLV, again because of lower metals collection efficiency.

Cobalt and nickel exceeded their respective TLVs but neither was detected in the fuel. Several other metals were also found in the effluents in lower concentrations, but were not found in one or both fuels. The following are possible explanations for this phenomenon:

(1) Leaching of elements from the SASS train or dilution tunnel.

(2) As mentioned in the section concerning atomic absorption, some blanks contained materials which appeared in the effluents but not in either fuel, thus unequal subtraction of blank from sample values could contribute to the apparent concentration of these elements.

Iron	Iron salts, soluble (as Fe)
Cobalt	Metal, dust and fume (as Co)

(3) The high temperatures attained on combustion may facilitate leaching of elements from the walls of the heaters.

(4) These elements may have been present in a fuel previously burned in these heaters. This is doubtful however, since they were new units.

(5) Contamination of the sample may be occurring although this is unlikely given the consistent levels of some of these elements.

(6) A combination of the above or some other mechanism altogether.

It should be pointed out that although several elements appear in the effluents which are not in the fuels, there are not any elements found in the fuel which are not in the effluents.

If the SSMS and ICAP values in Table 19 are compared using the factor of 3 criterion for a match, 45 percent are found to do so. Two points should be considered, however. First, that SSMS data include determination of elements in the XAD-2 which was not analyzed by ICAP. Therefore, SSMS should indicate higher values than ICAP. Secondly, if only SSAS train samples are compared, 65 percent of the SSMS and ICAP data match.

Date Analyzed 7-5-81

Calculations and Report Reviewed By R. J. Jakobsen

Report Date 7-31-81

Instrument Digilab FTS-10

Sample Cell Type Film on KBr plate

Utilized Max/Min Signal Intensity Values

Observations

Large amounts of what appears to be a primary amine salt. Significant amount of aliphatic hydrocarbon and carbonyl. The carbonyl is probably a mixture of ester and acid. Small amount of olefin and aromaticity.

Carboxylic acid				10-0.014	10-0.01	100-0.58	10-0.02	0.58
Acid salt							100-0.22	0.22
Primary amine salt						10-0.06		

[1] Concentration for gas samples = mg/m^3, for liquid samples = mg/L, for solid samples = mg/kg. Fill in actual m^3, L, or kg value.

ORGANIC EXTRACT SUMMARY REPORT

Contractor Battelle Columbus Laboratories

Sample Site EPA;RTP **Sample Acquisition Date** 6-25-81

Type of Source Air atomizing/automotive

Test Number E062581 **Sample ID Number** DREA-BCL-DF31/42-E062581

Sample Description Dilution filters #31 through 42.

Original Sample Volume or Mass 148.6g

Analyst Responsible R. L. Barbour **Date Analyzed** 7-24-81 **Time**

Calculations and Report Reviewed By R. J. Jakobsen **Report Date** 7-31-81

ORGANIC EXTRACT SUMMARY TABLE

Sample DREA-BCL-DF13/42-E062581

	LC1	LC2	LC3	LC4	LC5	LC6	LC7	Σ
Total Organics, mg	36.84	2.43	6.90	9.03	5.07	54.88	2.22	117.37
TCO, mg	0.07	0.01	0.09	0.29	0.37	0.83	0.58	2.24
GRAV, mg	36.77	2.42	6.81	8.74	4.70	54.05	1.64	115.13

Category	Assigned intensity – mg/m^3							
Aliphatic hydrocarbon	100-0.32	100-0.02	100-0.06	100-0.08	100-0.04	100-0.47	100-0.02	1.01

TECHNICAL REPORT DATA (Please read Instructions on the reverse before completing)		
1. REPORT NO. EPA-600/7-83-026	2.	3. RECIPIENT'S ACCESSION NO.
4. TITLE AND SUBTITLE Chemical Analysis of Waste Crankcase Oil Combustion Samples		5. REPORT DATE April 1983 6. PERFORMING ORGANIZATION CODE
7. AUTHOR(S) R. L. Barbour and W. M. Cooke		8. PERFORMING ORGANIZATION REPORT NO.
9. PERFORMING ORGANIZATION NAME AND ADDRESS Battelle-Columbus Laboratories 505 King Avenue Columbus, Ohio 43201		10. PROGRAM ELEMENT NO. 11. CONTRACT/GRANT NO. 68-02-2686, Task 133
12. SPONSORING AGENCY NAME AND ADDRESS EPA, Office of Research and Development Industrial Environmental Research Laboratory Research Triangle Park, NC 27711		13. TYPE OF REPORT AND PERIOD COVERED Task Final; 5/81-5/82 14. SPONSORING AGENCY CODE EPA/600/13

15. SUPPLEMENTARY NOTES IERL-RTP project officer is Robert E. Hall, Mail Drop 65, 919/541-2477.

16. ABSTRACT The report gives results of a study of emissions from waste crankcase oil heaters. The data provided should be useful to heater manufacturers and to regulators. Burner design and fuel composition affect the level of inorganic elements emitted. The vaporizing pot burner retained a significant amount of the trace elements in the pot residue, whereas the air-atomizing burner allowed more of the trace elements to be carried by the flue gas into the stack. The study also showed that total organic emissions from the two burner designs are similar; however, higher levels of polynuclear aromatic hydrocarbons (PAHs) were in discharges of the vaporizing pot burner.
